The difficult concussion patient: what is the best approach to investigation and management of persistent (>10 days) postconcussive symptoms?

Michael Makdissi,¹,² Robert C Cantu,³ Karen M Johnston,⁴ Paul McCrory,¹ Willem H Meeuwisse⁵

ABSTRACT
Background Concussion in sport typically recovers clinically within 10 days of injury. In some cases, however, symptoms may be prolonged or complications may develop. The objectives of the current paper are to review the literature regarding the difficult concussion and to provide recommendations for an approach to the investigation and management of patients with persistent symptoms.

Methods A qualitative review of the literature on concussion in sport was conducted with a focus on prolonged recovery, long-term complications and management including investigation and treatment strategies. MEDLINE and Sports Discuss databases were reviewed.

Results Persistent symptoms (>10 days) are generally reported in 10–15% of concussions. This figure may be higher in certain sports (eg, ice hockey) and populations (eg, children). In general, symptoms are not specific to concussion and it is important to consider and manage coexistent pathologies. Investigations may include formal neuropsychological testing and conventional neuroimaging to exclude structural pathology. Currently, there is insufficient evidence to recommend routine clinical use of advanced neuroimaging techniques or genetics markers. Preliminary studies demonstrate the potential benefit of sub symptom threshold activity as part of a comprehensive rehabilitation programme. Limited research is available on pharmacological interventions.

Conclusions Cases of concussion in sport where clinical recovery falls outside the expected window (ie, 10 days) should be managed in a multidisciplinary manner by healthcare providers with experience in sports-related concussion. Important components of management, after the initial period of physical and cognitive rest, include associated therapies such as cognitive, vestibular, physical and psychological therapy, assessment for other causes of prolonged symptoms and consideration of a graded exercise programme at a level that does not exacerbate symptoms.

INTRODUCTION
Over the past decade, recommendations for the management of concussion in sport have centred on physical and cognitive rest until symptoms resolve and then a graded programme of exertion prior to medical clearance and return to play.¹–³ This basic approach works well for the majority of concussions where clinical features resolve progressively within 10 days. In a number of cases, however, recovery can be prolonged or complications may develop. Persistent symptoms following concussion are a cause of significant morbidity and frustration to the athlete and pose a management challenge to the clinician. While there has been an explosion of studies on the acute management of concussion over the past decade, data on the management of prolonged recovery remain sparse. The current management approach to the difficult concussion is largely based on anecdotal evidence or extrapolation from studies on moderate-to-severe traumatic brain injury (TBI).

The objectives of the current study were to review the literature regarding the difficult concussion and to provide recommendations for an approach to the investigation and management of patients with persistent symptoms.

METHODS

The search was limited to the English language and focused on original papers published in the past 10 years. Reference lists from retrieved articles were searched for additional articles, and the authors’ own collections of articles were included in the search strategy.

RESULTS
Persistent postconcussive symptoms
Concussion typically results in a range of symptoms and signs in a number of different domains.¹–³ The clinical features vary, but commonly reported symptoms include headache, nausea, dizziness and balance problems, blurred vision, confusion, memory disturbance, mental ‘fogginess’ and fatigue.⁴–⁹ Prospective cohort studies and systematic reviews have consistently demonstrated that the majority of cases of concussion in adult populations resolve within 10 days of injury.⁴–⁹–¹² A ‘difficult concussion’ can be described as one in which clinical recovery falls outside the expected window (ie, 10 days).

The incidence of prolonged clinical recovery following concussion varies depending on the cohort.
being investigated (as well as the time frame used to define ‘prolonged’). Studies have shown that approximately 10–15% of collegiate and professional American football players have symptoms beyond 10 days.\(^7\)\(^-\)\(^9\)\(^\)\(^6\) Higher rates of prolonged recovery (ie, over 30% of cases) have been reported following concussion in ice hockey,\(^6\) and in cohorts of high school athletes.\(^14\)\(^\)\(^\)\(^\)\(^13\)

Common persistent symptoms include headache, depression, ‘difficulty concentrating’, ‘fatigue or low energy’, ‘difficulty sleeping’ or ‘feeling not quiet right, in a fog or slowed down’.\(^4\)\(^-\)\(^9\)\(^\)\(^10\)\(^\)\(^13\)\(^\)\(^16\) These symptoms are non-specific and may be reported in healthy athletic populations at baseline (table 1) and in patients with other injuries, illnesses or neuropsychiatric conditions. These same symptoms have also been reported in general trauma patients, individuals with anxiety or depression, patients with chronic pain syndromes, soldiers with combat stress and individuals who are involved in litigation regardless of the type of injury.\(^17\)\(^-\)\(^25\)

When assessing postconcussion symptoms, it is important to consider that reporting of symptoms may be affected by a number of factors including sex, socioeconomic factors, concurrent illness or musculoskeletal injury and moderate-to-high intensity exercise.\(^18\)\(^-\)\(^29\) Studies in patients with mild TBI have also demonstrated that symptom reporting can be influenced by general health status,\(^10\) other medical conditions such as migraines,\(^31\) and psychological factors such as coexisting anxiety and depression.\(^3\)\(^2\)

The method used for symptom reporting can also impact on the results. For example, Krol and Mrazik\(^33\) performed a cross-sectional study in 117 athletes comparing self-reported symptoms to symptoms endorsed during an interview. The authors found a higher number of symptoms reported and a greater overall symptom score in the self-administered condition.\(^33\) They also found that athletes reported more symptoms when the interviewer was woman.\(^33\) Similarly, Iverson et al\(^28\) demonstrated a higher reporting of symptoms on a self-administered questionnaire when compared with a structured interview in a cohort of athletes with concussion.

General health questionnaires that incorporate patient-reported outcome measures in a number of domains (eg, depression, anxiety, etc) have been used in the study of retired players.\(^3\)\(^16\) Given the complex nature of postconcussion symptoms, similar questionnaires may also be beneficial in the assessment of difficult concussions. Domains that should be considered in this assessment include:

- Depression and anxiety (eg, Hospital Anxiety and Depression Scale, Beck Depression Inventory, Depression Anxiety Stress Scale, Profile of Moods States);
- Headache and migraine (Headache Impact Test, Migraine Disability Assessment);
- General health and disability (eg, Short-form 36 Health Survey Questionnaire, Health-Related Quality of Life);
- Sleep (eg, Medical Outcomes Study Sleep Scale Survey);
- Drug and alcohol use/abuse (eg, Drug Abuse Screening Test, Alcohol Use Disorders Identification Test).

The advantages of a more detailed, semiquantitative assessment are that it may help identify other causes or contributing factors to the individual’s symptoms and may facilitate monitoring over time. While specific patient-reported outcome measures have yet to be validated in concussion, they may serve as useful clinical and research assessment tools.

### Role of investigations

The assessment of recovery following concussion is currently limited by the absence of simple and reliable direct measures of brain function. Instead, clinicians must rely on indirect measures to inform clinical judgement, such as the symptoms and signs of concussion (including neurological and balance assessments), in addition to the use of brief neuropsychological tests to estimate the recovery of cognitive function.

#### Neuropsychological testing

Computerised screening neuropsychological test batteries have become an important component of concussion assessment.\(^1\)\(^-\)\(^3\) The test batteries have been shown to be sensitive to changes in cognitive function following concussion. Moreover, they have been shown to detect cognitive deficits in a significant proportion of individuals even after the symptoms have resolved.\(^9\)\(^\)\(^\)\(^\)\(^17\)

Although formal neuropsychological testing is also recommended in cases of concussion with persistent symptoms, there

is no literature on the test properties (sensitivity, specificity, predictive value, etc) in this setting.

Advanced imaging and investigation techniques
Advanced imaging and investigation techniques have demonstrated changes in brain function, activation patterns and white matter fibre tracts in cases of concussion with prolonged symptoms (table 2A). Often, these changes exist even when the athlete has recovered clinically and returned to sport (table 2B). As such, the significance of these changes remains unclear at this time. Nevertheless, advanced imaging and investigation techniques (such as Diffusion Tensor Imaging, functional MRI, MR spectroscopy, quantitative EEG, etc) may hold hope for future assessment protocols in concussion. In the short term, their use in the research setting should continue to be encouraged.

Genetic testing
Preliminary research reveals a potential association between genetics and long-term outcome following concussion. Apolipoprotein E (APOE) has been the most extensively studied gene in TBI. Jordan et al demonstrated a relationship between APOE4 genotype and chronic TBI score, particularly in high exposure boxers (ie, more than 12 professional bouts). Similarly, Kutner et al studied the potential influence of APOE4 genotype in a cohort of 53 active professional American footballers and found that players with at least one copy of the APOE4 allele scored lower on tests of attention and information processing speed and accuracy. In a neuropathological study of athletes with Chronic Traumatic Encephalopathy (CTE), an increased frequency of the APOE4 allele was noted among cases of pathologically confirmed CTE. Recently, however, a large case series did not find a definite relationship between the APOE4 genotype and CTE, especially in lesser grades of CTE.

Other genes that have been considered include the APOE promoter and Tau, with no consistent findings regarding an effect on outcome following concussion in sport.

Despite the methodological limitations of these studies, they provide preliminary evidence of a complex inter-relationship between head injury, genetics and the risk of cumulative damage. However, more research is required in this area before genetic testing can be recommended as part of the clinical work-up of concussion.

Management of structural injuries masquerading as concussion
Any athlete that sustains a head injury is at risk of having a structural brain injury (eg, brain contusion). One of the critical roles of the initial medical assessment is to examine the player neurologically for such injuries. There are well described and validated guidelines for the use of imaging in the acute stage following head injury (eg, the Canadian CT head Rule or the New Orleans Criteria). Furthermore, in athletes with persistent symptoms or cognitive deficits, consideration should be given to conventional neuroimaging to investigate for an underlying structural injury.

To date, there are no published studies evaluating treatment strategies in athletes who sustain structural head injuries. Consequently, decisions regarding their management, including return to play, should be made by a clinician experienced in structural brain injury and based on the type of injury (eg, fracture and haemorrhage), relative risks associated with return to sport and the presence of ongoing sequelae (eg, symptoms, signs, cognitive deficits). Structural brain injury is not a concussion. It requires further consideration outside of the realm of sport medicine expertise.

Treatment of persistent symptoms
Non-pharmacological treatment
The current treatment approach for difficult concussions is based largely on an extension of the guidelines for acute injuries (ie, rest until symptoms resolve, followed by the use of combined clinical measures of recovery to determine the timing of return to play). While an initial brief period of rest may be important in the management of acute concussion, there is limited evidence that further rest is beneficial in cases where clinical features are prolonged.

Conversely, preliminary evidence suggests that an active rehabilitation programme is useful for the management of concussion where the symptoms are prolonged (table 3). The rehabilitation programme is started even in the presence of symptoms.

The graded exercise test has also been demonstrated to have good inter-rater and test–retest reliability.

When dizziness or disequilibrium is a prominent feature of persistent symptoms following concussion, vestibular rehabilitation may be useful. In a cohort of individuals with blast-related mild TBI, Gottshall and colleagues demonstrated improvement in symptoms after an 8-week period of vestibular physiotherapy.

Other treatments have been used anecdotally for the management of specific symptoms. For example, manual or physical therapy may be used to treat myofascial pain or neck trigger points contributing to headaches; cognitive therapy including memory tasks as well as learning coping skills may be useful for some patients with persistent cognitive symptoms; and those who have problems with anxiety, panic attacks or other psychological or emotional problems may benefit from meditation, biofeedback or psychological therapy. At present, however, there are limited data on these techniques in the management of prolonged symptoms following concussion.

Pharmacological treatment
Numerous medications are available to treat the range of symptoms that are observed following concussion. Many of these medications have been investigated in patients with moderate or severe TBI, but there are few trials that have been conducted in mild TBI or concussion.

In a small cohort of volunteers diagnosed with major depression following mild TBI, Fam et al demonstrated an improvement in symptoms and function with the use of sertraline.

In a recent retrospective study, Reddy et al examined the effects of amantadine in 25 adolescent athletes with postconcussion symptoms that persisted longer than 21 days. Individuals were compared with historical controls, and all individuals were assessed using a computerised neurocognitive test battery. The authors showed that the group treated with 100 mg of amantadine twice per day demonstrated greater improvements in their reaction time, verbal memory and symptom reporting.

A number of different antimigraine treatments have been assessed in small studies of patients with headaches following mild TBI (table 4). The studies all report moderate to good results, but the findings have not been confirmed in larger randomised control trials, and nor have they been trialled specifically in patients with persistent symptoms following concussion in sport.

Components of a comprehensive concussion clinic
Current consensus advocates a multifaceted clinical approach to the assessment of concussion. This is perhaps even more

important in the setting of prolonged symptoms, where the diagnosis is not always clear (ie, there are other causes of prolonged symptoms) or when superimposed factors lead to a pattern of deterioration rather than the expected improvement. Some components of a comprehensive concussion clinic are summarised in table 5, although the list is by no means complete and expands with time and experience. For instance, access to expertise such as sport psychology, physiatry, psychiatry, occupational therapy, social work and educational consultants are now included in such a list. In addition, in the setting of the difficult concussion, access to appropriate rehabilitation strategies, both physical and cognitive, is important and identification of programme leadership and coordination is key. Community resources may be incorporated in addition to medical facilities.

Ideally, the concussion clinic would also have a central role in athlete and public education and health advocacy participating in collaborative efforts. Access to academic studies, as well as participating in and benefiting from research findings, helps to nurture the future directions of such a programme and benefits the injured athlete. The physical and administrative structure and support to the programme will facilitate excellence in the provision of care.

### SUMMARY AND RECOMMENDATIONS

A ‘difficult concussion’ can be described as one in which clinical recovery falls outside the expected window (ie, 10 days in the adult population).

#### Assessment of persistent symptoms

Persistent symptoms are non-specific and may be caused by or contributed to by other conditions (such as migraine, mental health issues, concurrent injuries, etc). The assessment of persistent symptoms therefore requires a careful history (including both past and family history) and examination (including assessment of the cervical spine and vestibular function). The current post concussion symptom checklist on the SCAT2 alone is insufficient for the assessment of persistent symptoms, without a detailed history of the symptoms. The addition of patient-reported outcome measures to the assessment battery in prolonged or difficult cases (especially in the case of the retired player with ongoing cognitive issues) would provide a more comprehensive, quantifiable approach to assessment and may allow identification of other causes or contributing factors to the patient’s symptoms.

TBI, traumatic brain injury.

Role of investigations
Neuropsychological testing remains as an important component of assessment following concussion. Formal neuropsychological testing should be encouraged in the difficult concussion, although there are limited data to support its recommendation at present.

Conventional imaging should be considered in any athlete with persistent symptoms or cognitive deficits to investigate for an underlying structural injury.

Advanced imaging and investigation techniques have demonstrated changes in small cohorts of patients with persistent symptoms, as well as in individuals after clinical recovery following concussion. At present, the clinical significance of these changes remains unclear. The current literature does not support the use of these investigation tools in the routine clinical management of athletes with concussion. Advanced imaging and investigation techniques do, however, contribute to our understanding of the pathophysiology of concussion, and ongoing use should be encouraged in the research setting.

Treatment
Currently, there is no evidence that prolonged rest is beneficial for patients with persistent symptoms. Preliminary studies demonstrate that an active rehabilitation programme may be useful for the management of cases where symptoms are prolonged.

The important components of an active rehabilitation programme include:
- Commencement even in the absence of complete symptom resolution;
- Prescriptive advice regarding the intensity, duration and timing of exercise;
- Working to a level that does not aggravate the symptoms (subsymptom threshold exercise);
- Slow progression of rehabilitation with monitoring of clinical outcome.

Currently, there is limited evidence for the use of pharmacotherapy in concussion. Medications should be limited to cases that do not resolve with a conservative approach, or those with severe symptoms at rest that preclude the start of a graded rehabilitation programme. Medications generally should be restricted to the management of related syndromes (eg, migraine, sleep disturbance, etc).

Difficult concussions should be managed in a multidisciplinary manner. Ideally, this is in the setting of a concussion clinic with access to expertise in a wide range of areas.
